ABSTRACT: Poly(1-vinylimidazole) reacts with silicic acid and poly(silicic acid), giving rise to water-soluble complexes and insoluble composites because of hydrogen bonding. The composition, structure, and morphology of the obtained products have been studied with elemental analysis, Fourier transform infrared spectroscopy, and scanning electron microscopy. The main direction of the reaction depends not only on the initial ratio of the components, concentration, and pH but also on the sequence of the reagent mixing: the presence of poly(1-vinylimidazole) macromolecules during the formation of silicic acid stabilizes soluble complexes, which precipitate with an excess of H₂SiO₄ only. These soluble complexes may serve as a pattern of particles responsible for the transport of silicic acid in diatom algae and other organisms that assimilate silicon from the environment. © 2005 Wiley Periodicals, Inc. INTRODUCTION

Interactions between inorganic polymeric hydroxides and organic macromolecules have been intensively studied recently in the following areas:

- The synthesis of materials with developed surfaces.¹⁻⁸
- The design of composite materials, including systems with the mixing of components on a molecular level (nanocomposites).⁹⁻²²
- Basic research of biomineralization.²³⁻⁴⁰

A great number of publications deal with silicon-containing systems as silicon is the second most widespread element on Earth, its compounds are easily available, and the resulting materials are valuable for electronics, solid-phase organic synthesis, chromatography, and so forth. Silicon alkoxides are the most popular precursors for the synthesis of polysiloxane structures¹⁻⁵,⁷,¹⁰⁻₁₂,¹⁵,⁴¹ because they allow to be involved in the reaction a lot of commercial polymers that are soluble in organic solvents. The interaction of water-soluble polymers with poly (silicic acid) (PSA) is less studied despite the evident advantage of synthesis in a water medium with inexpensive inorganic silicates. Such reactions are also important for understanding silicon assimilation from the environment by living organisms (diatoms, sponges, and others). The main studies in this area are related to the research of the structure and morphology of the finished composites from previously prepared PSA sols.⁴²⁻⁴⁸ Investigations concerning the initial stages of the reaction with monomeric silicic acid giving rise to primary soluble complexes are few in number.⁴⁹⁻⁵⁴

We used poly(1-vinylimidazole) (PVI) as the subject of study in this article. This polymer is a
weak base ($pK_{BH^+} = 5–6$). Its peculiar features in comparison with aliphatic amines are negligible protonation within the neutral pH range and a high capacity for hydrogen bonding. At the same time, imidazole structures are widely spread in nature. 1-Vinylimidazole and its polymers have been produced on a commercial scale since the 1960s. Silicic acid was generated by the neutralization of sodium silicate ($Na_2SiO_3$), which allowed us to study two routes of the reaction: the complexation of the previously obtained PSA with PVI and the formation of silicic acid in the presence of PVI with possible competitive condensation reactions in the solution and on the matrix of the organic polymer.

**EXPERIMENTAL**

PVI (molecular mass = 160,000) was obtained according to ref. 58 by the radical polymerization of the monomer in benzene. $Na_2SiO_3 \cdot 9H_2O$ was recrystallized from water before use.

Potentiometric measurements were performed on a Multitest ionometer with a combined pH electrode in a temperature-controlled cell at 20 ± 0.02 °C. Fourier transform infrared (FTIR) spectra were recorded on a Bruker IFS25 spectrometer (KBr pellets). Quantum chemical calculations were accomplished by the PM3 method within the framework of the unrestricted Hartree–Fock method with the Hyper-Chem 3.0 program with full optimization of geometry. Samples for scanning electron microscopy (SEM) were placed on stubs cooled with liquid nitrogen, dried in vacuo, and coated with gold in a SDC 004 (Balzers). SEM analysis was performed with a Philips SEM 525M.

**RESULTS AND DISCUSSION**

The neutralization of alkali metal silicates with strong acids in a water medium causes the rapid formation of oligomeric PSA particles. After the introduction of PVI into this system, complexes of two types may be formed (Fig. 1). Relatively short PSA chains can react with PVI, forming soluble interpolymeric complexes (route A), which are converted into a composite precipitate with the further condensation of silanol groups. On the other hand, the reaction of larger and branched PSA oligomers with PVI must cause directly insoluble products (route B). Indeed, the addition of solutions obtained by the acidification of 0.035 M $Na_2SiO_3$ with hydro-
chloric acid to 0.01 M PVI of the same pH gives rise to a precipitate (Fig. 2) with PSA concentrations of 2–17%, depending on the pH of the mixed solutions. The further titration of PVI with PSA solutions is accompanied by an increase in the pH and amount of the precipitate. The pH increase is likely due to the condensation of silanol groups under the action of the PVI matrix:

\[
\text{Si} - \text{O}^{-} + \text{HO-Si} \rightarrow \text{Si-O-Si}^{-} + \text{OH}^{-}
\]

\[
\text{Si}-\text{OH} + \text{HO-Si} \rightarrow \text{Si-O-Si}^{-} + \text{H}_{2}\text{O}
\]

These reactions must provide the elimination of alkali or a concentration decrease of acidic silanol groups, depending on the pH. The formation of hydrogen bonds with imidazole moieties also suppresses the dissociation of PSA and may lead to the observed increase in pH as in the case with poly(acrylic acid).56,57

In contrast to the system with preliminary neutralized Na2SiO3, the titration of its mixture with PVI is homogeneous even with a 15% excess of silicate, and only at a high PVI concentration (0.05 M) is it possible to obtain a precipitate during a day of storage (Table 1). Such facts seem to be unusual as PVI readily forms insoluble complexes with linear polymeric acids.56,57 In the case of PSA, additional crosslinking by a polysiloxane net is expected. An increase in the Na2SiO3 concentration in the mixture up to a 40% excess results in a precipitate at pH 8 that dissolves below pH 4.

PVI is a relatively weak base, and its titration curve in water does not have an inflection at the neutralization point [Fig. 3(a), curve 1]. Titration curves of PVI–Na2SiO3 mixtures lie above the PVI curve, having an additional inflection point that is more visible as a minimum in differential curves [Fig. 3(b)]. The dependence between the position of these additional inflection points and the component ratio [Fig. 3(c)] tends to be limited at Si/PVI = 0.6. This indicates an increase in the basicity of some PVI units under complexing with PSA. The possible mechanism of additional stabilization of protonated azole cycles includes hydrogen bonding with silanol oxygen [Fig. 4(b)]. Quantum chemical calculations show that the formation energy of the isomeric structure is 19 kcal/mol higher without this hydrogen bond [Fig. 4(a)]. The proposed structure is in agreement with titration data [Fig. 3(c)], which indicate an increase in the basicity during the complexing of approximately half of the PVI units. The partial protonation of the organic polymer also causes a pH increase and the aforementioned anomalous solubility of PVI–PSA complexes upon the addition of PSA to PVI solutions. The activity of siloxane
Oxygen in hydrogen bonding was mentioned earlier.\textsuperscript{61,62}

Of particular interest is the ability of PVI to give soluble complexes with PSA at a neutral pH as a model of one of the stages of the biosilification process. In the case of diatoms, soluble forms of PSA as a complex with biopolymers are supposed to explain silica transfer from the cell membrane to the growing valve.\textsuperscript{63} Polymeric amines and highly basic proteins isolated from

\textsuperscript{a} Initial PVI concentration = 0.01 (runs 1–3 and 8–10) or 0.05 M (runs 4–7); concentration of Na\textsubscript{2}SiO\textsubscript{3} (or PSA) = 0.03 (runs 1–3 and 8–10) or 0.05 M (runs 3–7); HCl concentration for neutralization = 1 (runs 1–7) or 0.1 M (runs 8–10).

Figure 3. pH versus $\chi = [\text{HCl}]/[\text{PVI units}]$ at titration of PVI–Na\textsubscript{2}SiO\textsubscript{3} mixture after neutralization point of sodium silicate (a), differential curves (b) and dependence of inflection points ($\chi_{\text{eq}}$) on Si/PVI ratio (c). Initial Si/PVI ratio: 0 (1), 0.075 (2), 0.10 (3), 0.33 (4), 0.44 (5), 0.67 (6), 0.93 (7), 1.17 (8), 1.42 (9), 1.13 in 0.1 M NaCl (10). Starting PVI concentration was 0.0075 M. 0.1 M HCl was used as titrant.
Diatom cell walls\textsuperscript{29,31,35,39,40} may serve as transporters of silicic acid coming through the cell membrane in a monomeric form and condensing by mechanism A (Fig. 1). It is also known\textsuperscript{64} that the pH value is decreased to 5 in the growing valve, and this causes the weakening of the PSA complex with biopolymers and results in PSA condensation on existing silica particles.

Table 1 contains data on the composition of PVI–PSA precipitates obtained from both previously neutralized Na\textsubscript{2}SiO\textsubscript{3} and a PVI–Na\textsubscript{2}SiO\textsubscript{3} mixture. Precipitates formed with a PVI excess have a nearly equimolar ratio of azole units and silicon, whereas with a excess of silicate or PSA, it is possible to obtain products enriched with silica. Evidently, only particles with completely bonded PVI units are insoluble, and excessive silicon-containing component can embed into products by the creation of three-dimensional polysiloxane nets.

IR spectra of PVI, solid PSA, and a 1:1 PVI–PSA composite are shown in Figure 5. The PVI spectrum contains bands of stretching vibrations of imidazole cycles (1500, 1406, 1286, and 1228 cm\textsuperscript{-1}), stretching vibrations of azole C–H (1110 and 1082 cm\textsuperscript{-1}), and bending vibrations of heterocycles (917, 827, and 744 cm\textsuperscript{-1}).\textsuperscript{65} The PSA spectrum also agrees with literature data: bands at 1082 (with a shoulder at 1200 cm\textsuperscript{-1}) and 800 cm\textsuperscript{-1} correspond to Si–O stretching motions, adsorption at 470 cm\textsuperscript{-1} can be attributed to a bending Si–O–Si mode, and vibrations of the Si–OH bond are observed at 960 cm\textsuperscript{-1}. In the case of the PVI–PSA composite, azolic bands are slightly shifted with respect to the PVI spectrum, and this is due to hydrogen bonding between silanol moieties and imidazole units. These are only hydrogen bonds; as in the case of protonation of PVI in the solid state, large changes in the IR spectra must happen.\textsuperscript{65} The silanol band shifts from 960 cm\textsuperscript{-1} in PSA to...
974 cm\(^{-1}\) in the spectrum of the composite, and this is also explained by hydrogen bonds. The optical density of the Si—OH band increases in the spectrum of the composite (with respect to the Si—O band at 470 cm\(^{-1}\)) in comparison with solid PSA obtained under similar conditions. The condensation of silicic acid in the presence of a donating polymer probably promotes the formation of more linear products with a higher content of silanol moieties.

According to SEM data (Fig. 6), the structure of the composite precipitates depends on the method of their synthesis. The addition of previously neutralized Na\(_2\)SiO\(_3\) to a PVI solution gives rise to aggregated particles with a size less than 100 nm [Fig. 6(A)], which corresponds to the presence of one PVI macromolecule in the composite particle. Evidently, the reaction of primary PSA particles with polymeric chains results in fast crosslinking and precipitation.

The neutralization of Na\(_2\)SiO\(_3\) in the presence of PVI in an equimolar ratio at high initial concentration (0.05 M) leads to the formation of 2–4-μm spherical particles [Fig. 6(B)]. In case of lower concentrations, the precipitate is formed only the next day, consisting of smaller particles [Fig. 6(C)]. As mentioned previously, under these conditions, the PVI reaction with silicic acid is likely to give mainly linear products, which can aggregate to large particles at high initial concentrations. The aggregation slows at lower concentrations, and the transformation of PVI–PSA complexes takes place with the formation of a three-dimensional polysiloxane net. The precipitate contains submicrometer particles [Fig. 6(C)]. The PVI–Na\(_2\)SiO\(_3\) system with a silicate excess occupies an intermediate state: its neutralization under stirring conditions causes a precipitate consisting of bars and large particles of irregular elongated, ellipsoidal, or cylindrical

Figure 6. SEM data: (A) a composite obtained by the addition of PSA to a PVI solution, (B,C) particles formed during the neutralization of Na\(_2\)SiO\(_3\) in the presence of PVI in equimolar concentrations (0.05 and 0.01 M, respectively), and (D) precipitated particles from a PVI–Na\(_2\)SiO\(_3\) mixture (1:1.4) after neutralization under vigorous stirring. The scale bars represent (A,C,D) 1 and (B) 10 μm.
shapes, the surface of which is sometimes covered with submicrometer granules [Fig. 6(D)]. Large particles are probably formed from relatively linear PVI–PSA complexes as in the case of an equimolar composition. However, the high rate of condensation and precipitation stabilizes nonequilibrium elongated structures connected with vigorous stirring of the solution. Submicrometer granules on the surface of large particles are formed because of the condensation of PSA excess.

CONCLUSIONS

The interaction of a weak organic polybase with silicic acid proceeds as a set of parallel reactions: condensation in a solution giving rise to PSA nanoparticles and their interaction with the polymer and the condensation of silicic acid on the organic matrix, causing the formation of soluble products able to further aggregate. The prevalent way of the process depends not only on the component ratio, concentration, and pH but also on the order of reagent mixing: the presence of PVI macromolecules during silicic acid formation stabilizes soluble complexes, which precipitate in an excess of H4SiO4 only. The morphology of PVI–PSA composite precipitates depends on the nature of the primary particles. Therefore, the interaction of previously formed PSA with organic macromolecules results in aggregated nanoparticles less than 100 nm in diameter. On the other hand, the neutralization of Na2SiO3 in the presence of PVI is accompanied by relatively slow precipitation with larger particles.

The authors are very thankful to M. A. Grachev, a member of the Russian Academy of Sciences, for target setting and fruitful discussion of the results. They also thank the Presidium of the Russian Academy of Sciences for its financial support (projects 10.3 and 25.5).
